ABSTRACT
We propose SecNav, a new protocol for securing wireless navigation systems. This protocol secures localization and time-synchronization in wireless networks by relying on devices’ awareness of presence in the power-range (coverage area) of navigation stations. We perform a detailed security analysis of SecNav and we show that, compared to existing secure navigation approaches, it prevents the widest range of attacks on navigation.

1. INTRODUCTION
The use of location and time information in wireless networks is broad and ranges from enabling networking functions (e.g., position-based routing) to enabling location-related applications (e.g., access control, data harvesting, emergency and rescue). Researchers have therefore proposed a number of positioning and time-synchronization techniques for wireless networks, based on a wide range of technologies, including measurements of the strength and time of propagation of radio and ultrasonic signals.

However, recently, researchers have demonstrated that localization and time-synchronization techniques are highly vulnerable to signal manipulation attacks. To cope with this problem, a number of solutions were proposed, relying on bidirectional communication between the infrastructure and nodes and on unidirectional (broadcast) navigation signals. Bidirectional communication helps in reducing the set of possible attacks on localization and time synchronization, notably, through the use of security primitives like distance-bounding, authenticated ranging, and delay estimations; these primitives can be used to efficiently prevent pulse-delay attacks on synchronization and signal replay attacks on localization.

In broadcast-based navigation schemes, however, such bidirectional primitives cannot be used and these scheme become therefore highly vulnerable to attacks based on navigation signal replays. Range-free localization scheme by Lazos et al. is vulnerable to selective signal replay attacks, especially if jamming of navigation beacons cannot be detected by the localized devices. This problem was partially addressed by Kuhn in the context of securing range-based navigation, where the replay of individual navigation signals is prevented by a late disclosure of signal spreading codes. However, this solution is vulnerable to replays of aggregated navigation signals.

In this work, we propose SecNav, a novel secure navigation protocol, based on navigation signal broadcasts, which does not require bidirectional communication between the infrastructure and navigation devices. We show that this protocol prevents a wide range of attacks on localization and time synchronization, including location spoofing attacks using aggregated signal replays. SecNav relies on integrity coding and on devices’ awareness of their presence in the coverage area of navigation stations (e.g., within a building, university campus, or a city). We show how this coding prevents message manipulation attacks and protects the integrity and the authenticity of transmitted navigation messages. We further show how the requirement of devices’ and users’ awareness of presence in the (wider) coverage area of the infrastructure can be efficiently ensured in a number of applications. To the best of our knowledge, SecNav is also the first secure broadcast-based time synchronization system for local-area and sensor networks.

We present two instances of SecNav: SecNav-R, which secures range-based localization, and SecNav-F, which secures range-free localization. SecNav can be implemented with a wide range of existing wireless radio technologies, including 802.11 and Zigbee technologies.

The application domain of SecNav is wide; this system can be effectively used for secure indoor and outdoor localization and synchronization of individual wireless devices, whose communication is supported by an infrastructure (e.g., WiFi devices), but also for localization and synchronization in multi-hop sensor and ad-hoc networks. Although intended primarily for smaller local environments (e.g., com-
company buildings, university campuses), with appropriate technologies and legislation in place, SecNav can be equally used in wider areas (e.g., smaller cities).

The rest of this paper is organized as follows. In Section 2, we describe our system and the attacker models and we state the observed problem. In Sections 3 and 4, we describe our secure navigation system. In Section 5, we present the security analysis of SecNav. In Section 6 we describe the related work. Finally, we conclude the paper in Section 7.

2. SYSTEM MODEL AND PROBLEM STATEMENT

Before stating our problem, we first describe the observed system.

2.1 System model

Our system consists of a set of stations forming a navigation infrastructure which provides radio signals that enable devices to determine their location and to obtain an accurate time reference. We assume that navigation stations are tightly synchronized and emit navigation signals, based on which navigation devices determine their location and time reference. Like in GPS, we assume that navigation stations are tightly synchronized and emit navigation signals simultaneously (up to a measurable drift). Each navigation signal $s_i$ contains a timestamp $t_i$ of the time at which it was sent and a location $L_i$ of the base station $BS_i$, that sent it. Upon collecting at least four signals and registering their reception times, the navigation device calculates the distances to the stations, and determines its location $p$ and time reference by multilateration.

This is illustrated on Figure 1. The cumulative signal observed at the navigation device at time $t$ is given by the following expression:

$$ r(p, t) = \sum_i A_i(p, t) \cdot s_i(t_i - \frac{|L_i - p|}{c} + \delta) + n(p, t) $$

where $A_i(p, t)$ and $n(p, t)$ are the strength of the signal $s_i$ and the noise at location $p$ and time $t$, respectively; $\delta$ is the desynchronization error between the device and the navigation stations, and $c$ is the speed of light in vacuum. Upon the reception of a navigation signal from station $BS_i$, the device registered its reception time $t'_{i}$, from which it computes a pseudo range $d_i$ to $BS_i$, as

$$ d_i = (t'_{i} - t_i) \cdot c $$

Each pseudo-range contains (the same) error $c \cdot \delta$ introduced by the offset $\delta$ between the device’s and stations’ clocks. By measuring pseudo-ranges to (at least) four stations, the device can determine it’s location $p$ and the synchronization offset $\delta$ and therefore synchronize to the stations. This is done by solving (for $p$ and $\delta$) the system of (at least four) following equations

$$ d_i = |L_i - p| + c \cdot \delta $$

2.1.1 Range-based localization

Here, we consider navigation systems that have the same or similar mode of operation as the GlobalPositioning System (GPS) [14]. This means that in these systems, stations emit navigation signals, based on which navigation devices determine their location and time reference. Like in GPS, we assume that navigation stations are tightly synchronized and emit navigation signals simultaneously (up to a measurable drift). Each navigation signal $s_i$ contains a timestamp $t_i$ of the time at which it was sent and a location $L_i$ of the base station $BS_i$, that sent it. Upon collecting at least four signals and registering their reception times, the navigation device calculates the distances to the stations, and determines its location $p$ and time reference by multilateration. This is illustrated on Figure 1. The cumulative signal observed at the navigation device at time $t$ is given by the following expression:

$$ r(p, t) = \sum_i A_i(p, t) \cdot s_i(t_i - \frac{|L_i - p|}{c} + \delta) + n(p, t) $$

where $A_i(p, t)$ and $n(p, t)$ are the strength of the signal $s_i$ and the noise at location $p$ and time $t$, respectively; $\delta$ is the desynchronization error between the device and the navigation stations, and $c$ is the speed of light in vacuum. Upon the reception of a navigation signal from station $BS_i$, the device registered its reception time $t'_{i}$, from which it computes a pseudo range $d_i$ to $BS_i$, as

$$ d_i = (t'_{i} - t_i) \cdot c $$

Each pseudo-range contains (the same) error $c \cdot \delta$ introduced by the offset $\delta$ between the device’s and stations’ clocks. By measuring pseudo-ranges to (at least) four stations, the device can determine it’s location $p$ and the synchronization offset $\delta$ and therefore synchronize to the stations. This is done by solving (for $p$ and $\delta$) the system of (at least four) following equations

$$ d_i = |L_i - p| + c \cdot \delta $$

2.1.1 Range-based localization

Here, we consider navigation systems that have the same or similar mode of operation as the GlobalPositioning System (GPS) [14]. This means that in these systems, stations emit navigation signals, based on which navigation devices determine their location and time reference. Like in GPS, we assume that navigation stations are tightly synchronized and emit navigation signals simultaneously (up to a measurable drift). Each navigation signal $s_i$ contains a timestamp $t_i$ of the time at which it was sent and a location $L_i$ of the base station $BS_i$, that sent it. Upon collecting at least four signals and registering their reception times, the navigation device calculates the distances to the stations, and determines its location $p$ and time reference by multilateration. This is illustrated on Figure 1. The cumulative signal observed at the navigation device at time $t$ is given by the following expression:

$$ r(p, t) = \sum_i A_i(p, t) \cdot s_i(t_i - \frac{|L_i - p|}{c} + \delta) + n(p, t) $$

where $A_i(p, t)$ and $n(p, t)$ are the strength of the signal $s_i$ and the noise at location $p$ and time $t$, respectively; $\delta$ is the desynchronization error between the device and the navigation stations, and $c$ is the speed of light in vacuum. Upon the reception of a navigation signal from station $BS_i$, the device registered its reception time $t'_{i}$, from which it computes a pseudo range $d_i$ to $BS_i$, as

$$ d_i = (t'_{i} - t_i) \cdot c $$

Each pseudo-range contains (the same) error $c \cdot \delta$ introduced by the offset $\delta$ between the device’s and stations’ clocks. By measuring pseudo-ranges to (at least) four stations, the device can determine it’s location $p$ and the synchronization offset $\delta$ and therefore synchronize to the stations. This is done by solving (for $p$ and $\delta$) the system of (at least four) following equations

$$ d_i = |L_i - p| + c \cdot \delta $$
where each equation corresponds to one pseudo-range \( \hat{d} \) measured by \( B \) to station \( BS_i \). This is illustrated on Figure 2a.

### 2.1.2 Range-free localization

We further consider range-free broadcast navigation systems. These systems are similar to range-based localization in that the navigation device determines its location and synchronizes to the infrastructure based on the messages that it receives from navigation stations. The main difference is that, instead of measuring distances to the stations, the device simply registers from which stations it received the messages and then estimates its location within the area defined by the intersection of the power ranges of navigation stations. This is illustrated on Figure 2b. Examples of range-free localization schemes include the proposals of He et al. in [17] and Lazos et al. in [24]. Similarly, the device synchronizes to the infrastructure by simply adjusting its clock to the timestamp contained in the received beacons. One example of time synchronization using reference broadcast is described in [9].

### 2.2 Attacker model

We adopt the following attacker model. We assume that the attacker Mallory \((M)\) controls the communication channel in a sense that he can eavesdrop messages, insert messages, modify and schedule transmitted messages. More specifically, we assume that the attacker can relay and delay transmitted messages. We do assume that the attacker cannot disable the communication channel between infrastructure nodes and navigation devices (e.g., use a Faraday’s cage to block the propagation of radio signals). However, the attacker can jam all transmissions and in that way prevent the transmission of the information contained in the message; the receiver will therefore still receive the message from the sender, superimposed by the attacker’s messages. Our attacker model is similar to the the Dolev-Yao model [8] in that the attacker controls the communication channel, but it differs in that the attacker cannot trivially remove the energy of emitted signals from the channel, especially if these signals are unpredictable. We detail this in Section 5.2.

### 2.3 Attacks on navigation systems

Main security threats to navigation systems are caused by the forgery and replay of navigation signals. If signals can be forged by the adversary, she can present navigation devices with a set of signals corresponding to any location and time. With appropriate message authentication and integrity protection mechanisms, message forgery can be prevented. However, even with signal authentication, navigation systems remain insecure due to possible signal replay attacks (which cannot be prevented using traditional authentication and integrity protection mechanisms). Specifically, in systems based on time-of-arrival (like in the one described above) signals can be relayed and delayed by the attacker. The simplest form of message replay attack is the pulse-delay attack [51, 13]. In this attack, the attacker registers the original time-stamped signal \( s \) sent by the infrastructure station and replays it to the attacked receiver, but with a delay \( \delta \) (in some scenarios, for this attack to succeed the attacker also needs to jam or overshadow the original signal). Here, by signal overshadowing we mean that the original message will appear as noise in the attacker’s (much stronger) signal. The computed pseudo-range at the receiver will therefore be artificially increased by \( c \cdot \Delta \) and will be computed as follows.

\[
\hat{d} = |L_i - p| - c \cdot \delta + c \cdot \Delta,
\]

(4)

If all (four) signals are appropriately delayed by the attacker, the device will estimate its location at a spoofed location \( p' \). This is illustrated on Figure 3a. Pulse-delay attacks have particularly severe impact on localization techniques based on time-of-arrival (TOA) and on time-difference-of-arrival (TDOA) techniques.

Another form of signal replay attack is the replay of aggregated navigation signals obtained from other locations. In this attack, the attacker creates a fast wormhole [20] between the location which it wants to convince the device of, and the actual location of the attacked device. The relayed signal will be stronger than the original navigation signal at devices’ true location (i.e., it will overshadow the original signal) and will therefore make the device believe that it is located at the location from which the signal is relayed.
This attack is illustrated on Figure 3b.

Several solutions have been proposed to prevent replay attacks, based on signal spreading [23] and on authenticated ranging or distance-bounding [52, 51]. Solution based on signal spreading prevents pulse-delay attacks, but it is vulnerable to replays of aggregated navigation signals. Solutions based on authenticated ranging/distance bounding prevent both attacks, but require bi-directional communication between the infrastructure and the receivers.

### 2.4 Problem statement

Now we state our problem: How can a device $B$, securely determine its location and time reference in the presence of an attacker $M$, based on signals received by the infrastructure? Note that in solving this problem, we focus on the above described localization systems, in which devices compute their locations and time reference based on signals emitted by the navigation infrastructure. We therefore consider scenarios in which localization and synchronization are performed passively by the devices (i.e., devices do not emit any signals in order to determine their location or to synchronize with the infrastructure).

### 3. SECNAV-R: SECURE RANGE-BASED BROADCAST NAVIGATION

In this section, we describe SecNav-R, a novel system for securing localization and time synchronization in broadcast navigation systems. SecNav-R is based on time-of-flight measurements and, in terms of location and time computations, operates as described in Section 2.1.1. In SecNav-R, navigation stations are therefore mutually synchronized, cover a given physical space, and transmit navigation signals containing station locations and timestamps. Devices that reside in the station’s coverage area collect navigation signals, determine pseudo-ranges, and process them in real-time to obtain their locations and time reference. In this respect, SecNav is similar to other existing navigation systems. However, what makes SecNav-R significantly different is the fact that the navigation signals emitted by the stations are specifically encoded using integrity-codes [48] to eliminate the threat of replay attacks; integrity codes consist of Manchester coding and on-off keying on the physical layer that also enable straightforward detection of message overshadowing attacks. Besides with integrity codes, navigation messages in SecNav-R are also protected using digital signatures, which prevent message forging attacks.

In the following section, we describe the process of encoding of the navigation signal in SecNav-R.

### 3.1 Signals Encoding

We explain the process of integrity-coding of navigation signals through an example shown in Figure 4. In this example base station $BS_i$ wants to transmit a navigation message $m_i(t_s) = BS_i∥t_s∥L_i$, containing its identifier $BS_i$, message sending time $t_s$, and its location $L_i$ to navigation devices in its vicinity. Before sending the message, $BS_i$ first appends it with the message signature $\text{sig}_{X} \{m_i(t_s)\}$, generated with the infrastructure private key $K_X$. Before emitting $m_i(t_s)$, $\text{sig}_{X} \{m_i(t_s)\}$ over a radio channel, $BS_i$ transforms this message as follows: it applies Manchester (complementary) encoding rule to $m_i(t_s), \text{sig}_{X} \{m_i(t_s)\}$ that is, each bit “1” of $m_i(t_s)$ is encoded as 10 and each bit “0” as 01. The resulting message is denoted with $c_i(t_s)$ in Figure 4. Manchester encoding ensures that resulting message $c_i(t_s)$ consists of equal number of bits “1” and “0”. Finally, in order to transmit $c_i(t_s)$ over a radio channel, $BS_i$ uses on-off keying modulation at the physical layer. Thus, for each symbol “1” of $c_i(t_s)$, the sender emits a random waveform during the symbol period $T$ (a fresh random waveform is generated for each symbol), and for each symbol “0” of $c_i(t_s)$, the sender is silent (does not emit any signals) during the period $T$.

In order to retrieve the transmitted message, the navigation device ($B$) simply measures the energy in the corresponding time slots of duration $T$. Let $P_i$ denote the average power that the receiver measures in a given time slot of duration $T$. Let us also denote with $P_0$ and $P_1$ pre-defined threshold power levels. Here, $P_1 \geq P_0$. For the given time slot, the receiver $B$ decodes the received signals as follows:

1. if $P_i \geq P_1$, output symbol “1”
2. if $P_i \leq P_0$, output symbol “0”
3. else reject.

Here, the receiver listens on the predefined channel and for each time slot of duration $T$ it applies the above decoding rule to obtain message $c_i(t_s)$. Finally, the receiver uses the inverse of Manchester encoding rule (i.e., 01 $\rightarrow$ 0, 10 $\rightarrow$ 1) to retrieve the navigation message $m_i(t_s)$. 

![Figure 4: SecNav navigation message encoding. The navigation message is first encoded using Manchester coding resulting in message $c_i(t_s)$, which is then transmitted on the wireless channel using on-off keying (signal $s_i(t_s)$). On-off keying is implemented such that for each “1” of $c_i(t_s)$, the station emits a random waveform during the symbol period $T$ (a fresh random waveform is generated for each symbol), and for each symbol “0” of $c_i(t_s)$, the sender is silent (does not emit any signals) during the period $T$.](image-url)
The protection of the navigation signal \( m_i(t_s) \), \( \text{sig}_{K_N} \{ m_i(t_s) \} \) here comes from the fact that simultaneous presence of two different I-coded messages \( m_i(t_s) \) and \( \hat{m}_i(t_s) \) in the same area necessarily results in an incorrectly demodulated message at a receiver. Thus, an adversary, in order to change \( m_i(t_s) \) into a fake message \( \hat{m}_i(t_s) \neq m_i(t_s) \), has to change at least one bit of \( m_i(t_s) \) (i.e., \( \hat{m}_i(t_s) \) differs in at least one bit). This implies that the corresponding \( c_i(t_s) \) and \( \hat{c}_i(t_s) \) will differ in at least two bits. Moreover, at least one bit “1” of \( c_i(t_s) \) has to be converted into “0” in \( \hat{c}_i(t_s) \). In other words, the adversary has to annihilate (cancel out) the waveform representing a bit “1” of \( c_i(t_s) \), otherwise the receiver cannot correctly demodulate the message received at the physical layer and it will simply reject it. By appropriately crafting waveforms representing bits “1” (e.g., by making these waveforms random), the task of canceling them out can be made arbitrarily hard for the adversary.

Digital signatures make it even more difficult for the attacker to modify navigation messages. In the presence of digital signatures, the attacker can only attempt to convert the original message \( m_i(t_s) \) into a message \( \hat{m}_i(t' < t_s) \) that was already sent by the station in the past, and cannot forge a new message. This is important especially for secure time synchronization, as it prevents that the clocks of navigation devices are shifted ahead by the attacker; digital signatures cannot, however, prevent that the local clocks of the devices are shifted back in time. Besides adding to the security of navigation systems, digital signatures in SecNav add to the robustness of the message transmission. Signatures act as redundancy checks for the messages, and can also be used for message reconstruction, if local interference modifies messages in transmission (e.g., turns symbols 0 to 1).

Note here that we assume the navigation signal of BS \( i \) to “always” be present in the observed area. Otherwise, an adversary could easily insert his/her fake navigation message. We elaborate further on this in Section 3.3.

To verify the integrity and authenticity of the demodulated navigation message \( m_i(t_s) \), the receiver needs to:

1. verify that it resides in the infrastructure coverage area
2. verify that the channel on which it received the signal \( s_i(t_s) \) is the channel used by the infrastructure
3. verify that the demodulated message \( c_i(t_s) \) is valid, i.e., it contains an equal number of bits “1” and “0”
4. verify that the demodulated signature \( \text{sig}_{K_N} \{ m_i(t_s) \} \) correspond to the demodulated message \( m_i(t_s) \)

If these conditions are fulfilled, device \( B \) concludes that the navigation message \( m_i(t_s) \) is authentic and has been transmitted by the navigation station BS \( i \). Conditions (i) and (ii) are generally fulfilled by dissemination of public information; namely, the wider area that the infrastructure covers and the channels that the stations use can be made publicly available (or disseminated) by a trusted authority. Condition (iv) is fulfilled by appropriate dissemination of the infrastructure public key. Condition (iii) therefore remains the most important criterion for the verification of message authenticity and integrity. As we argued at the end of the previous section, this condition ensures that if the Manchester encoded message \( c_i(t_s) \) contains an equal number of bits “1” and “0”, then it has not been modified in transmission. This is due to the on-off keying modulation and signal anti-blocking property which prevent bits “1” from being flipped, and enable the detection of signal overshadowing attacks.

3.2 Computing the Location and Time Reference

Upon the reception of the navigation message, the navigation device registers the message reception time \( t'_r \) (the reception time of the first bit of the message), verifies its authenticity and integrity (as described earlier) and extracts from the message its sending time \( t_s \). From four message sending and reception times, the station computes four pseudoranges.

\[
(t'_r - t_s) \cdot c = |L_1 - p| + c \cdot \delta \\
(t'_r - t_s) \cdot c = |L_2 - p| + c \cdot \delta \\
(t'_r - t_s) \cdot c = |L_3 - p| + c \cdot \delta \\
(t'_r - t_s) \cdot c = |L_4 - p| + c \cdot \delta
\]

By solving this system of equations, the station computes its location \( p \) and the time difference \( \delta \) between its clock and the clocks of the stations. Here, \( t'_r \) are the navigation signal reception times, \( L_i \) are the locations of navigation stations and \( c \) is a speed of light in vacuum. An example diagram of message reception times at the receiver is shown on Figure 5. Here, we assume that, similarly to GPS receivers [14], navigation devices in our system can receive navigation signals simultaneously on at least four channels (one channel for each navigation station).

Thus far, we have observed that each station BS \( i \) transmits a single navigation signal \( s_i(t_s) \) at time \( t_s \). However, in our system, the absence of legitimate navigation signals in the infrastructure coverage area would enable an attackers to...
insert messages and provide false reference to navigation devices in that area. To prevent this, in our scheme each navigation station is required to keep the channel busy by either transmitting valid navigation messages in uninterrupted sequence or by transmitting I-coded sequences that will prevent the attacker from forging any meaningful messages on that channel. Note, however, that in this case there has to be a way for the navigation station BS$_i$ to inform the receiver B about the beginning and the end of any message c$_i(t_s)$ emitted over the channel. In our navigation system SecNav, this is achieved by means of the incongruous-delimiter (I-delimiter). In the following section, we show how navigation stations (BS$_i$) and navigation devices (B) can use I-delimiters in order to synchronize securely with respect to the beginning and the end of the transmission of the given message c$_i(t_s)$.

### 3.3 SecNav Message Synchronization via Incongruous-Delimiter (I-delimiter)

Assuming that the station transmits sequences of navigation messages, we implement the navigation message delimiters which enable navigation stations (BS$_i$) to recognize the start and the end of each message (even if the messages vary in length). We introduce message delimiters through the following example. Let us assume that the station wants to transmit the following two codewords consecutively

\[
\begin{align*}
c_i(t_s) &= 1010011001 \\
c_i(t_s + \Delta t) &= 1010010101
\end{align*}
\]

which, under Manchester encoding rule, correspond to navigation messages $m_i(t_s) = 11010$ and $m_i(t_s) = 11000$, respectively. The station BS$_i$ simply emits (using on-off keying - see Figure 4) the following sequence

\[
\text{delimiter } c_i(t_s) \text{ delimiter } c_i(t_s + \Delta t) \text{ delimiter}
\]

\[
\ldots 111000 \quad 1010011001 \quad 111000 \quad 1010010101 \quad 111000 \quad \ldots
\]

Here, the “delimiter=111000” is a specially constructed bit string such that any successfully demodulated codeword$^1$ received between any two consecutive “delimiters” is authentic. This is true as the delimiter sequence 111000 cannot appear as a part of any correctly encoded message nor can it be forged by an adversary, given that the adversary cannot convert bits “1” to “0” (see Section 5.2). This effectively prevents the adversary from “shifting” delimiters in time and thus forging transmitted navigation messages without being detected.

In the following section, we present the range-free SecNav (SecNav-F).

### 4. SECVNAV-F: SECURE RANGE-FREE BROADCAST NAVIGATION

Secure Range-Free Broadcast Navigation (SecNav-F) relies on the same message (Integrity) coding as SecNav-R. Navigation messages in SecNav-F have the same format as those in SecNav-R and are equally separated by I-delimiters (Section 3.3).

---

$^1$In our example, by “successfully demodulated codeword” we mean the codeword for which the transformation $(10 \rightarrow 1, 01 \rightarrow 0)$ exists.

---

![Figure 6: Secure Time Synchronization with SecNav-F. To synchronize with the infrastructure station BS$_i$, the receiver (B) sets its local clock Cl$_B = t_s - t_f - t_r$.](image)

In SecNav-F, every navigation station BS$_i$ transmit navigation messages $m_i(t_s) = BS_i||t_i||L_i$ containing its identifier BS$_i$, message sending time $t_s$ and its location $L_i$ to navigation devices in its vicinity. This message is appended with the message signature $sig_{K_{BS}}(m_i(t_s))$, generated with the infrastructure private key $K_N$. Before emitting $m_i(t_s)$, $sig_{K_{BS}}(m_i(t_s))$ over a radio channel, BS$_i$ transforms this message using integrity coding as shown on Figure 4.

The navigation device collects messages from stations for a predefined time period of duration $\Delta t$. Upon receiving messages from at least three (four in the case of 3D localization) navigation stations, the device starts their verification and the computation of its location. The duration of $\Delta t$ is set by the wireless device and it depends on device’s speed of displacement.

The device first demodulates navigation messages and verifies their integrity and authenticity by performing the same four message verification steps as in SecNav-R: (i) verifies that it resides in the infrastructure coverage area, (ii) verifies that the channel on which it received the signal $s_i(t_s)$ is the channel used by the infrastructure, (iii) verifies that the demodulated message $c_i(t_s)$ is valid, i.e., it contains an equal number of bits “1” and “0” and (iv) verifies that the demodulated signature $sig_{K_{BS}}(m_i(t_s))$ correspond to the demodulated message $m_i(t_s)$. If these verifications are successful the navigation device computes its location $(x_B', y_B')$ within the area defined by the stations’ ranges. This is illustrated on Figure 2b. One example of such computation is the Minimum Mean Square Estimate (MMSE), which computes the devices location as follows:

\[
\text{Let } f_i(x_B', y_B') = R - \sqrt{(x_i - x_B')^2 + (y_i - y_B')^2}
\]

The location $(x_B', y_B')$ is then obtained by minimizing $F(x_B', y_B') = \sum_{BS_i \in S} f_i^2(x_B', y_B')$ over all estimates $(x_B', y_B')$.
neously. Stations, however, do send navigation messages continuously.

In SecNav-F, for a navigation device to synchronize to the infrastructure it is sufficient that it receives messages from at least one of the navigation stations. It then adjusts its local clock $Cl_F$ as follows:

$$Cl_F = t_s - t_p - t_r,$$

where $t_s$ is the timestamp contained in the navigation message, $t_p$ is the message transmission time (which depends on the message length and on the transmission speed) and $t_r$ is the message propagation time (which depends on the distance between the station and the device); $t_r$ is typically few nanoseconds, and it can therefore be neglected in most applications. Time Synchronization in SecNav-F is illustrated on Figure 6.

5. SECURITY ANALYSIS

As we already noted, in SecNav, attacks on localization are prevented by the construction of the codes used to encode navigation signals and by devices’ awareness of presence in the coverage area of the infrastructure. In the following security analysis, we will assume that devices and/or users are aware of their presence in the infrastructure coverage area.

As we already described in Section 2, navigation systems are vulnerable to a range of attacks by manipulation of navigation signals.

In SecNav, message forgery, manipulation and replay is prevented through permanent transmissions of navigation signals on the communication channel. By permanent presence of legitimate navigation messages on all four communication channels and over the entire infrastructure coverage area, the attacker is prevented from inserting false navigation messages, without being detected. If the attacker inserts its (false) navigation message, this message will interleave with navigation messages sent by the infrastructure. The receivers will therefore reject the received superposition of two messages because the ratio of the number of symbols 1 and 0 in that message will be different from the one expected at the receivers. Essentially, any message forged by the attacker, replayed, or simply modified in transmission will be equally rejected at the receiver as it will change the ratio of the number of 1s and 0s in the received message. Following the same reasoning, we can conclude that the replay of aggregated navigation signals will be equally prevented. These aggregated navigation signals will interleave with legitimate navigation signals sent by the infrastructure and will cause the receivers to reject the received signals. If the device is unknowingly displaced from the infrastructure coverage area, message forgery is still prevented by the use of digital signatures. However, in our scenario, we assume that the devices are aware of their presence in the coverage area of the infrastructure, e.g., on campus; in Section 5.1 we detail how this is ensured.

Since message replay and forgery are prevented in SecNav, attacks on localization and time-synchronization by pulse-delays are equally prevented. E.g., if pulse-delay is attempted by jam-and replay, this will be detected at the receivers as the messages replayed by the attacker will be superimposed to the legitimate messages sent by the infrastructure. Given that to detect bits 0 and 1 on the channel, receivers measure strengths of the messages (as opposed to their signal-to-noise ratio), attacks by message overshadowing will be equally detected. Pulse-delay attacks with message overshadowing will therefore be equally detected.

5.1 Awareness of presence

Although SecNav effectively prevents attacks by manipulation of navigation signals, there are some physical attacks that SecNav cannot prevent. One example of such an attack is when the attacker cuts-off node’s communication to the navigation infrastructure (either by replacing the node out of infrastructure coverage area, or by placing it into a Faraday cage) and then feeds it with false navigation signals. If the users control their devices, that kind of attacks are highly unlikely. If, however, the devices are autonomous, such attacks are hard to prevent, irrespective of the navigation system, unless the devices can detect displacement and/or encapsulation.

SecNav relies on the devices awareness of presence in the infrastructure coverage area. In the case of user-centric applications, the knowledge of this coverage area can be made known to the user by a trusted authority; the user can then use the system only within the intended area. In the case of autonomous devices, what suffices is that they are once initiated within the infrastructure coverage area, where they can securely obtain their location; the devices can then be programmed never to leave the intended area. Attacks involving physical removal of the autonomous devices from the coverage area can be prevented by requiring devices to occasionally check their proximity to the navigation stations by means of e.g., authenticated ranging [52] or distance bounding [2] (these techniques do, however, require occasional bidirectional communication between the infrastructure and mobile devices). Alternatively, these attacks can be prevented by the use of motion detectors and/or inertial navigation systems [6].

5.2 Preventing the attacker from erasing symbol “1”

So far, we showed that any message manipulation by the attacker will result in the ratio between the number of “0”s and “1”s being changed in the message, resulting in the message rejection at the receiver. Here, we assumed, notably, that the attacker is not able to convert symbol “1” into “0”, but is only able to convert symbol “0” into “1”. This scheme provided integrity protection of transmitted messages and implicitly also enabled the verification of their authenticity.

In order to erase the signal (symbol “1”) from the channel, the attacker needs to be able to predict the shape of the signal at the receiver and send the inverted signal to the receiver to cancel it out (see Figure 4). There are several major factors that make it difficult for the attacker to erase the signal from the channel: the randomness of the channel, the randomness of the signal generated at the sender and the mobility of the navigation device.
To prevent the attacker from erasing the signal, we implement the following scheme: the sender randomizes the signals corresponding to symbols “1”. Specifically, to prevent signal erasure, each symbol “1” of the I-coded message $c$ is transmitted as a random signal of duration $T$. Note that we can randomize amplitude, phase, frequency etc. Given the randomness of this signal, it is difficult for the attacker to flip symbol “1” to “0” as it would need to predict the shape of the random signal in order to cancel it. In [48], we analyzed in greater detail the effects of the randomness of the radio signal on the attacker’s ability to erase the signal from the channel.

6. RELATED WORK

In the last decade, a number of indoor localization systems were proposed, based notably on infrared [55], ultrasound [56, 36], received radio signal strength [1, 18, 4] and radio time-of-flight [26, 11] techniques. These localization techniques were also extended to wireless ad hoc networks [7, 3, 50, 34, 41, 33, 10, 5, 31].

Recently, a number of secure distance and location verification schemes have been proposed. Brands and Chaum [2] proposed a distance bounding protocol that can be used to verify the proximity of two devices connected by a wired link. Sastry, Shankar and Wagner [40] proposed a distance bounding protocol, based on ultrasonic and radio wireless communication.

Kuhn [23] proposed an asymmetric security mechanism for navigation signals, based on hidden message spreading codes. Lazos et al. [24] proposed a set of techniques for secure positioning of a network of sensors based on directional antennas. Both these approaches, however, remain vulnerable to attacks including the replay of aggregated navigation signals. Capkun and Hubaux [51, 52] propose a technique called verifiable multilateration, based on distance-bounding, which enables a local infrastructure to verify positions of the nodes. In [57], describe a similar technique, focusing on using ultra-wide-band ranging. Lazos et al. [25] propose an extension of their work in [24] that copes with the replay of navigation signals. In [54], Capkun et al. propose a secure localization scheme based on hidden and mobile base stations. Although these techniques prevent message replays, they assume bi-directional communication between the infrastructure and the devices and require that stations and devices are equipped with fast processing ($O(n^2)$) hardware. We pose no such requirements in SecNav-F. For SecNav, we require similar processing speed as found in GPS receivers. Li et al. [27] and Liu et al. [28] propose statistical methods for securing localization in wireless sensor networks. These techniques assume a limited attacker that can only modify a fraction of navigation messages exchanged between the nodes. If this fraction is reasonably small, then the proposed solutions can detect outliers and perform successful localization. We do not make such assumptions in SecNav.

In [43], Sedighpour et al. demonstrated the feasibility of distance reduction and enlargement attacks on ultrasonic ranging systems. Recently, a number of proposals have also been made to protect the anonymity and location privacy of wireless devices [37, 15, 38, 39, 21, 22].

Similarly to localization, time synchronization has equally been thoroughly studied, especially in the context in sensor networks [46]. In this context, there are several prototype implementations, such as RBS [9], TPSN [12], FTSP [30], that can achieve synchronization precision of a few microseconds.

In [13] time synchronization techniques have been shown to be vulnerable to signal manipulation attacks, similar to those that affect localization. Several solutions emerged to detect such attacks; in [13] Ganelwal et al. propose and implement a secure time synchronization scheme for sensor networks that effectively detects pulse-delay attacks. Similar solution was later proposed by Sun et al. in [45]. In [29], authors analyze the impact of malicious attacks on time synchronization to sensor network applications and middleware services such as shooter localization. All these solutions assume bi-directional communication between a reference node and the synchronized node (or between the infrastructure and the synchronized nodes). In SecNav, we do not make such assumptions. SecNav is therefore the first mechanisms for broadcast secure time-synchronization.

A more detailed overview of secure localization and secure time synchronization in wireless networks can be found in [35].

7. CONCLUSION

In this work, we proposed SecNav, a novel secure navigation protocol based on navigation signal broadcasts. We showed that this protocol prevents a wide range of attacks on localization and time synchronization, including message forgery and replay. We further showed that SecNav is the first navigation system that effectively prevents location spoofing attacks using aggregated signal replays.

SecNav is the first navigation system that relies on the devices’ awareness of presence in the infrastructure coverage area. So far, presence awareness was used to enable message origin authentication and secure key establishment in wireless networks [48, 53]; in this work, we showed that presence awareness equally helps to build localization and time-synchronization in the same networks.

The application domain of SecNav is wide; this system can be effectively used for secure in-door and outdoor localization and synchronization of individual wireless devices, whose communication is supported by an infrastructure (mobile nodes, WiFi devices), but equally for localization and synchronization in multi-hop sensor and ad-hoc networks. Although intended primarily for smaller local environments (e.g., company buildings, university campuses), with appropriate technologies in place, SecNav can be equally used in wider areas (e.g., smaller cities).
