Abstract
Generalized Algebraic Datatypes, or simply GADTs, can encode non-trivial properties in the types of the constructors. Once such properties are encoded in a datatype, however, all code manipulating that datatype must provide proof that it maintains these properties in order to typecheck. In this paper, we take a step towards gradualizing these obligations. We introduce a tool, Ghostbuster, that produces simplified versions of GADTs which elide selected type parameters, thereby weakening the guarantees of the simplified datatype in exchange for reducing the obligations necessary to manipulate it. Like ornaments, these simplified datatypes preserve the recursive structure of the original, but unlike ornaments we focus on information-preserving bidirectional transformations. Ghostbuster generates type-safe conversion functions between the original and simplified datatypes, which we prove are the identity function when composed. We evaluate a prototype tool for Haskell against thousands of GADTs found on the Hackage package database, generating simpler Haskell'98 datatypes and round-trip conversion functions between the two.

Categories and Subject Descriptors D.1.1 [Programming Techniques]: Applicative (Functional) Programming

Keywords GADTs, Datatypes, Haskell

1. Introduction
Languages in the Haskell, OCaml, Agda, and Idris traditions can encode complicated invariants in datatype definitions. This introduces safety at the cost of complexity. For example, consider the standard GADT (generalized algebraic datatype) formulation of length-indexed lists:

```haskell
data Vec a n where
  Nil   :: Vec a Zero
  Cons' :: a → Vec a n → Vec a (Succ n)
```

Although this datatype provides additional static guarantees—for example, that we cannot take the head of an empty list—writing functions against this type necessarily involves additional work to manage the indexed length type n. In some situations however, such as when prototyping a new algorithm, the user may prefer to delay the effort required to fulfill these type obligations until they can verify that the new algorithm is beneficial. In that case, we can convert the length-indexed list into a regular list by erasing the length index n and operating over a simplified representation:

```haskell
data Vec' a where
  Nil'  :: Vec' a
  Cons' :: a → Vec' a → Vec' a
```

before converting back to the original datatype in order to test the changes within the larger code base.

However, this final step requires re-establishing the type-level invariants that were encoded in the original datatype, which may not be straightforward. Perhaps the user should stick to regular ADTs for this project? Unfortunately, that too may not be an option. In the 16,183,864 lines of public Haskell code we surveyed, we found 11,213 existing GADTs. A person tasked with working in an existing project is unlikely to be able to reimplement all of a project’s datatypes and operations on them from scratch.

Inspired by the theory of ornaments [10, 15], we can think about moving between families of related datatypes that have the same recursive structure: rather than always working with a GADT, a user could choose to (initially) write code against a simpler datatype, while still having it seamlessly interoperate with code using the fancier one. A practical tool to do this could enable a gradual approach to discharging obligations of indexed datatypes. In this paper, we present such a tool. We require that it (1) define canonical simplified datatypes; and (2) create conversion functions between the original and simplified representations.

Is it possible to define such a simplification strategy by merely choosing which type indices to remove from a datatype? While such a method would be convenient for the user, it is far from obvious that there exists a class of datatypes for which such an erasure selection yields a canonical simplified datatype and guarantees that conversion functions can successfully round-trip all values of the GADT through the simplified representation and back.

In this work, we show how to do exactly that. Using our tool—named Ghostbuster—the user simply places the following pragma above the definition of Vec:

```
{-# Ghostbuster: synthetize n #-}
```

and Ghostbuster will generate the definition Vec' as well as conversion functions between the two representations:

```haskell
upVec :: Typeable n ⇒ Vec a n → Vec' a
downVec :: Typeable n ⇒ Vec' a → Maybe (Vec a n)
```

Since downVec may fail at runtime if the actual size of the vector does not match the expected size as specified (in the type n and checked at runtime via Typeable) by the caller, we return the result wrapped in Maybe, but we could also choose to throw an error on failure or return a diagnostic message using Either. If we do not know the specific type index that must be synthesized during...
the conversion process, we can keep it sealed under an existential binding and still make use of it in contexts that operate over any instance of the sealed type:

```
data SealedVec a where
  SealedVec n => Vec a n => SealedVec a
```

downVecS :: Vec a t => SealedVec a
withVecS :: SealedVec a -> Vec' b n. Vec a n -> b

Assuming we had such functionality, would that truly make our lives any easier, or have we just moved our type-checking responsibilities elsewhere? We will show that manipulating these simplified—or ghostbusted—datatypes is not at all burdensome, and can indeed make life simpler. As an example, consider implementing deserialization for our indexed list. With Haskell’98 datatypes such as Vec, a Read instance can be derived automatically, but an attempt to do so with the Vec GADT results in a cryptic error message mentioning symbols and type variables only present in the compiler-generated code. Disaster! On the other hand, by leveraging Ghostbuster we can achieve this almost trivially:

```
instance (Read a, Typeable n) => Read (Vec a n) where
  readsPrec s =
  [ (v,s) | (v',s) <- readsPrec i s,
              let v = downVec v' ]
```

In this paper we scale up the above type-index erasure approach to handle a large number of datatypes automatically. We make the following contributions.

- We introduce the first practical solution to incrementalize the engineering costs associated with GADTs.
- We give an algorithm for deleting any type variable that meets a set of non-ambiguity criteria. Our ambiguity criteria establish a gradual erasure guarantee: if a multi-variable erasure is valid, then any subset of these variables also forms a valid erasure (Section 5).
- We formalize the algorithm in the context of a core language. We show that up-conversion functions are total and up-then-down is exactly the identity function on all values in the original GADT (Section 6).
- We show how the encoding of dynamically typed values that emerges from the algorithm can be asymptotically more efficient than a traditional type Dynamic (Section 2.2).
- Viewed in the context of the literature on deriving type class instances for datatypes, Ghostbuster increases the reach of deriving capabilities beyond previous functional language implementations, by lifting derivations on simpler types to fancier ones, as with Read above (Section 3).
- We describe the Ghostbuster tool, currently implemented as a source-to-source translator for Haskell, but directly generalizable to other languages. We evaluate the runtime performance of Ghostbuster conversions compared to the ad-hoc approach to constructing GADTs using a runtime eval, and apply it to existing datatypes in all 9026 packages on the Hackage Haskell package server (Section 8).

Although our approach does not handle all datatypes or Haskell features, it clearly delineates the class of valid erasures and lays the groundwork for future research.

1 Admittedly, this instance would be improved if the constructors of our simplified datatype used the exact same names as the original, but we append an apostrophe to constructor and type names as a convention to clearly distinguish the generated, simplified datatypes.

2. Design Constraints

The central facility provided by Ghostbuster is a method to allow users to select a subset of type variables of a given GADT, from which we derive a new datatype that does not contain those type variables—they have been erased from the datatype. Furthermore, we generate an up-conversion function from the original datatype to the newly generated one, as well as a down-conversion function from the simplified type back to the original, re-establishing type-level invariants as necessary.

Before jumping into the details of how this is implemented, we first highlight some of the different problems that can occur when attempting to erase a type variable from a GADT, which will give us some intuition on the design constraints and behavior of Ghostbuster. Section 3 explores a larger example in more detail.

2.1 Prerequisite: Testing Types at Runtime

Ghostbuster blurs the line between having a statically-typed and dynamically-checked program. With Ghostbuster, we can explicitly remove type-level information in one part of the program (up-conversion), which we then re-establish at some later point (down-conversion). To accomplish this, a central requirement for Ghostbuster is the ability to examine types at runtime and to take action based on those tests. Haskell has supported (open-world) type representations for years via the Typeable class:

```
class Typeable a where
  typeRep :: proxy a -> TypeRep a
```

However, this is insufficient for our purposes because examining a TypeRep value gives us no type-level information about the type that value represents. Instead, we require a type-indexed type representation, which makes the connection between the two visible to the type system:

```
class Typeable a where
  typeRep :: TypeRep a
```

This type-indexed representation is currently in development for GHC and is scheduled for release as part of GHC-8.2.5 We assume the presence of this new design throughout the paper, although until this new Typeable design becomes available in GHC proper we generate these type-indexed TypeRep values ourselves.6

We can then use the following functions to compare two types and gain type-level information when those types are equal:

```
eqT :: (Typeable a, Typeable b) => Maybe (a :~: b) eqTT :: TypeRep a @ TypeRep b => Maybe (a :~: b)
```

data a :~: b where
  Refl :: a :~: a
```

2.2 Erasure Method: Checked versus Synthesized

The basic option that we provide to users is the ability to erase type variables from a GADT. However, there are restrictions on which type variables are valid erasure candidates. Consider the standard list:

```
{-# Ghostbuster: synthesize a #-} — invalid!
data List a where
  Nil :: List a
  Cons :: a -> List a -> List a
```

https://ghc.haskell.org/trac/ghc/wiki>Typeable

5 For simplicity our local TypeRep and Typeable definitions do make a closed-world assumption, but since we require only the interface we have shown here, and as will appear in GHC-8.2 for an open world of types, there is no loss of generality.

6 Additionally, the use of embedded TypeRep values rather than embedded Typeable class constraints simplifies our core language (Section 4).
If we remove the type parameter \( a \) and attempt to \emph{synthesize} it when converting back to the original datatype, we will find that it is not possible to write this down-conversion function. In contrast to our initial \texttt{Vec} example (Section 1), if we remove the information about the type of the list elements, we cannot infer that information based solely on the recursive structure of the list.

For this reason, we allow a second, weaker form of type index erasure. Given the declaration

\[
\texttt{data List' where}
\]

\[
\text{Nil' :: List'}
\]

\[
\text{Cons' :: } \forall a. \text{TypeRep } a \rightarrow a \rightarrow \text{List'} \rightarrow \text{List'}
\]

\[
\text{upList :: Typeable } a \Rightarrow \text{List } a \rightarrow \text{List'}
\]

\[
\text{downList :: Typeable } a \Rightarrow \text{List'} \rightarrow \text{List'}
\]

Ghostbuster will generate the following simplified representation of \texttt{List} together with its conversion functions:

\[
\text{data List' where}
\]

\[
\text{Nil' :: List'}
\]

\[
\text{Cons' :: } \forall a. \text{TypeRep } a \rightarrow a \rightarrow \text{List'} \rightarrow \text{List'}
\]

\[
\text{upList :: Typeable } a \Rightarrow \text{List } a \rightarrow \text{List'}
\]

\[
\text{downList :: Typeable } a \Rightarrow \text{List'} \rightarrow \text{List'}
\]

In contrast to \texttt{Vec'}, where the erased type was synthesized during down-conversion, when erasing type variables in checked mode we must \emph{embed} a representation of the type directly into the constructor \texttt{Cons'}, otherwise this information will be lost. We refer to the type parameter \( a \) as \emph{newly existential}, as it was not existentially quantified in the original datatype fed to Ghostbuster. It is \emph{only} newly existential type variables that require an explicit type representation to be embedded within the simplified datatype. This is important, as we surely do not want the user to have to create and manipulate \texttt{TypeRep} values for all erased parameters.

During down-conversion, we check that each element of the list does indeed have the same type the user expects:

\[
\text{downList :: } \forall a. \text{Typeable } a \Rightarrow \text{List'} \rightarrow \text{List'}
\]

\[
\text{downList Nil' } = \text{Just Nil}
\]

\[
\text{downList } (\text{Cons' } a' x x') = \text{do}
\]

\[
\text{Refl } \leftarrow \text{eqTT } a' \text{ (TypeRep } :: \text{TypeRep } a)
\]

\[
x s \leftarrow \text{downList } x x'
\]

\[
\text{return } (\text{Cons } x x)
\]

Compare this to the definition of our \texttt{down-conversion} for our original \texttt{Vec} datatype, which erased its type-indexed length parameter in synthesized mode:

\[
\text{downVecS :: } \forall a. \text{Vec } a \rightarrow \text{SealedVec } a
\]

\[
\text{downVecS } \text{Nil' } = \text{SealedVec } \text{Nil}
\]

\[
\text{downVecS } (\text{VCons'} x x') = \text{case } \text{downVecS } x x' \text{ of}
\]

\[
\text{SealedVec } x s \rightarrow \text{SealedVec } (\text{VCons } x x)
\]

\[
\text{downVec :: Typeable } n \Rightarrow \text{Vec } a \rightarrow \text{Maybe } (\text{Vec } a n)
\]

\[
\text{downVec } v' = \text{case } \text{downVecS } v' \text{ of}
\]

\[
\text{SealedVec } v \rightarrow \text{gcast } v
\]

This highlights the key difference between erasures in checked versus synthesized mode. In order to perform down-conversion on \texttt{List'} we must examine the type of each element and compare it to the type that we expect; thus, we can not create a \texttt{SealedList} which hides the type of the elements, since we would not know what type to compare against in order to perform the conversion. In contrast, down-conversion for \texttt{Vec'} \emph{does not} need to know a priori what the type \( n \) should be; only if we wish to open the \texttt{SealedVec} do we need to check (via \texttt{Data.Typeable.gcast}) that the type that was synthesized is indeed the type we anticipate.

\textbf{Connection to dynamic typing} We note that this embedded type representation essentially makes each list element a value of type \texttt{Dynamic}. Why then do we use explicit, \emph{unbundled} type representations when \texttt{Dynamic} has existed in Haskell for years? For the \texttt{List} type above, we would perform the same \( O(n) \) number of runtime type checks with either approach, but consider the following list-of-lists datatype:

\[
\text{data LL a where}
\]

\[
\text{NilL :: LL a}
\]

\[
\text{ConsL :: } [a] \rightarrow \text{LL a} \rightarrow \text{LL a}
\]

These two competing approaches would each yield the following simplified types for \texttt{ConsL}:

\[
\text{ConsL'\_\_\_ \_\_d y n :: } [\text{Dynamic}] \rightarrow \text{LL'} \rightarrow \text{LL'}
\]

\[
\text{ConsL'\_\_\_r e p :: } \text{TypeRep } a \rightarrow [a] \rightarrow \text{LL'} \rightarrow \text{LL'}
\]

Thus, during down-conversion the former would require a runtime type check on every element of the \emph{inner} list, whereas our unbundled representation requires only a single check for each element of the \emph{outer} list—an improvement in asymptotic efficiency. This is one reason that we design Ghostbuster to inject explicit type representations using \texttt{TypeRep}.

Finally, this observation suggests an appealing connection to gradual typing—when Ghostbusted, data structures that were refined by type indexing become regular, parametrically polymorphic data structures, which in turn become dynamic datatypes once all type parameters are erased.

\section{Unrecoverable Information}

Consider the following definition of a strange binary tree:

\[
\text{data Bad a where}
\]

\[
\text{Leaf :: } x \rightarrow \text{Bad } x
\]

\[
\text{Node :: } \text{Bad } y \rightarrow \text{Bad } z \rightarrow \text{Bad } z
\]

Here, only the rightmost leaf of the tree is usable, since every leftward branch is of some unknown, unusable type \( y \). According to our policy of embedding an explicit type representation for any newly-existent types (Section 2.2) we will add a \texttt{TypeRep} to the \texttt{Leaf} constructor to record the erased type \( x \). However, what type representation do we select for \( y \)? Since this type is already unknowable in the original structure we cannot possibly construct its type representation, so such erasures are not supported.

\section{A Policy for Allowed Erasures}

As we saw in Section 2.2, the defining characteristic of which mode a type variable can be erased in is determined by whether the erased information can be recovered from what other information remains. As a more complex example (which we explore further in Section 3) consider the application case for an expression language:

\[
\text{data Exp env ans where}
\]

\[
\text{App :: Exp e (a } \rightarrow \text{ b) } \rightarrow \text{ Exp e a } \rightarrow \text{ Exp e b}
\]

Why does the type \( e \) which is existentially quantified, not cause a problem? It is because \( e \) is a \emph{pre-existing} existential type (not made existential by a Ghostbuster erasure). The type \( a \) can be synthesized by recursively processing fields of the constructor, unlike the \texttt{Bad} example above. Thus, we will not need to embed a type representation so long as we can similarly rediscover in the simplified datatype the erased type information at runtime. This is an information-flow criterion that has to do with how the types of the fields in the data constructor constrain each other.

\textbf{Checked mode: right to left} In the \texttt{App} constructor, because the \texttt{env} type variable is erased in checked mode, its type representation forms an \texttt{input} to the \texttt{downExp} down-conversion function. This means that since we know the type \( e \) of the result \texttt{Exp e b} (on the right), we must be able to determine the \( e \) in the fields to the left, namely in \texttt{Exp e a} and \texttt{Exp e (a } \rightarrow \text{ b)}. Operationally, this makes sense if we think how the \texttt{downExp} function must call itself on each of the fields of the constructor, passing the (same) representation for the type \( e \) to each recursive call.
We might expect a sufficiently clever implementation to notice that should be erased during compilation. Irrelevance requires a whole-program and the types of the constructors encode both the type that that constructor will generate the types \( (a \rightarrow b) \) and a from the left, which in turn are used to determine the output type \( b \) on the right.

Fortunately, whether or not type variables \( a \) and \( b \) can be determined by examining the other types in the constructor is a purely local check that can be determined in isolation on a per-constructor/per-datatype basis.\(^5\) The same local reasoning holds for the requirements on checked types as well as synthesized. We formalize these information flow checks in Section 5.

**Erased types that escape** Ghostbuster performs one final check before declaring an erasure is valid: datatypes undergoing erasure can only be used directly in the fields of a constructor, not as arguments to other type constructors. For example, what should the behavior be if we attempt to erase the type variable \( a \) in the following:

```
data T a where
  MkT :: [T a] -> T a
```

We might expect a sufficiently clever implementation to notice that it can utilize the `Functor` instance to apply up-and-down-conversion to each element of the list. But what if the type constructor does not have a `Functor` instance, or is only exported abstractly, thereby prohibiting further analysis? This appears to be a tricky design space, so our current implementation simply rules out these erasures altogether.

### 3. Life with Ghostbuster

In this section, we describe several scenarios in which Ghostbuster can make life easier, taking as a running example the simple expression language which we define below.

#### 3.1 A Type-safe Expression Language

Implementing type-safe abstract syntax trees (ASTs) is perhaps the most common application of GADTs. Consider the following language representation:\(^6\)

```
data Exp env ans where
  Con :: Int -> Exp e Int
  Add :: Exp e Int -> Exp e Int -> Exp e Int
  Var :: Idx env t a -> Exp e a
  Abs :: Typ a -> Exp (e, a) b -> Exp e (a -> b)
  App :: Exp e (a -> b) -> Exp e a -> Exp e b
```

Each constructor of the GADT corresponds to a term in our language, and the types of the constructors encode both the type that that term evaluates to (a `data`) as well as the type and scope of variables in the environment (\( \text{env} \)). This language representation enables the developer to implement an interpreter or compiler which will statically rule out any ill-typed programs and evaluations. For example, it is impossible to express a program in this language which attempts to add two functions.

Handling variable references is an especially tricky aspect for this style of encoding. We use typed de Bruijn indices (\( \text{Idx} \)) to project a type \( t \) out of a type level environment \( \text{env} \), which ensures that bound variables are used at the correct type \( [5] \).

\[^3\] This is more local than other (tangentially related) features such as the `\( \_\)` notation in Idris \([5]\) and Agda, which signifies a type is runtime-irrelevant and should be erased during compilation. Irrelevance requires a whole-program check to verify whether the annotation can be fulfilled.

\[^4\] This is a simple world of types `Typ` containing `Int` and `\( \rightarrow \)`.

Using GADTs to encode invariants of our language (above) into the type system of the host language it is written in (Haskell) amounts to the static verification of these invariants every time we run the Haskell type checker. Furthermore, researchers have shown that this representation does indeed scale to realistically sized compilers: Accelerate \([8, 16, 17]\) is an embedded language in Haskell for array programming which includes optimizations and code generation all written against a GADT AST, maintaining these well-typed invariants through the entire compiler pipeline.

Where then does the approach run into trouble? The problem is that manipulating this representation requires the developer to discharge a (potentially non-trivial) proof to the type system that all of these invariants are maintained. As such, the programmer’s time may be spent searching for a type-preserving formulation of their algorithm, rather than working on the algorithm itself.

In the next section, we discuss how Ghostbuster can be used to realize the situation shown in Figure 1, where we wish to implement a prototype transformation over our expression language, without needing to discharge all of the typing obligations up front. Of course, other alternatives exist:

**Competing approach #1: hand-written conversions** Rather than using a tool such as Ghostbuster, a user could just as well build the same conversion functions to and from a less strictly typed AST representation themselves. Indeed, Ghostbuster itself is written entirely in Haskell, and no modifications to the GHC compiler were required to support it. However, this introduces a maintenance burden. Moreover, these conversion functions are tricky to implement, and since the Haskell type checker cannot stop us from writing ill-typed conversions to or from our untyped representation, these errors will only be caught when the runtime type tests fail.

**Competing approach #2: runtime eval** Another approach is to avoid the fine-grained runtime type checks necessary for down-conversion entirely, by generating the GADT term we require as a string, and using GHC embedded as a library in our program to typecheck (\( \text{eval} \)) the string at runtime. Implementing a pretty-printer is arguably less complex than the method we advocate in this work, but there are several significant disadvantages to this approach which we will demonstrate in Section 8.
class Syntactic f where
  varIn :: Idx env t → f env t
  expOut :: f env t → f env t
  weaken :: f env t → f (env, s) t

instance Syntactic Idx
instance Syntactic Exp

shift :: Syntactic f
  ⇒ (V t'. Idx env t' → f env' t) → Idx (env, s) t → f (env', s) t
shift _ ZeroIdx = varIn ZeroIdx
shift v (SuccIdx ixs) = weaken (v ixs)

rebuild :: Syntactic f
  ⇒ (V t'. Idx env t' → f env' t) → Exp env t → Exp env' t
rebuild v exp =
  case exp of
    Var ix → expOut (v ix)
    Abs t e → Abs t (rebuild (shift v) e)
    Abs t (Abs' t e) → Abs t (rebuild (shift v) e)
    Abs t (Var' ix) → Abs t (rebuild (shift v) e)
    Abs t (Add' a b) → Abs t (rebuild (shift v) e)
    Abs t (Mul' a b) → Abs t (rebuild (shift v) e)
    Abs t (Sub' a b) → Abs t (rebuild (shift v) e)
    Abs t (Con' n) → Abs t (rebuild (shift v) e)
    Abs t (Const' n) → Abs t (rebuild (shift v) e)
    Abs t (App' f a) → Abs t (rebuild (shift v) e)
    Abs t (App' f a b) → Abs t (rebuild (shift v) e)
    Abs t (App' f a b c) → Abs t (rebuild (shift v) e)

Listing 1. Substitution algorithm for richly-typed terms

3.2 Example #1: Substitution

Consider the task of inlining a term into all use sites of a free variable. For our richly-typed expression language, where the types of terms track both the type of the result as well as the type and scope of free variables, this requires a type-preserving but environment changing structure representation algorithm. Luckily, the simultaneous substitution method of McBride [14] provides exactly that, where renaming and substitution are instances of a single traversal, propagating operations on variables structurally through terms. Listing 1 outlines the method.

Although the simultaneous substitution algorithm is very elegant, we suspect that significant creativity was required to come up with it. Compare this to the implementation shown in Listing 2, which is a simple structural recursion on terms. In particular, this is implemented against the simplified representation generated by Ghostbuster using the erasure pragma.\(^7\)

\[\text{Ghostbuster: check env, synthesize ans \#-}\]

which yields the following expression datatype:

data Exp' where
  Con' :: Int → Exp'
  Add' :: Exp' → Exp' → Exp'
  Mul' :: Exp' → Exp' → Exp'
  Var' :: Idx' → Exp'
  Sub' :: Typ' → Exp' → Exp'
  App' :: Exp' → Exp' → Exp'

and conversion functions:

\(\text{shift} :: \text{Idx'} → \text{Exp'} → \text{Exp'}\)

\(\text{shift} j \text{exp} =\)

\(\text{case exp of}\)

\(\text{Var' } \text{ix} \mid \text{ix} < j \rightarrow \text{Var' } \text{ix}\)
\(\text{otherwise} \rightarrow \text{Var' } (\text{SuccIdx' } \text{ix})\)

\(\text{Abs' } \text{t} \text{e} \rightarrow \text{Abs' } \text{t} \text{(shift } (\text{SuccIdx' } j) \text{e})\)

\(\ldots\)

\(\text{substitute } :: \text{Exp'} → \text{Exp'} → \text{Exp'}\)

\(\text{substitute } = \text{go ZeroIdx'}\)

\(\text{where}\)

\(\text{go } j \text{old new} =\)
\(\text{case old of}\)

\(\text{Var' } \text{ix} \mid \text{ix} == j \rightarrow \text{new}\)
\(\text{ix} > j, \text{SuccIdx' } \text{i} ← \text{ix} \rightarrow \text{Var' } \text{i}\)
\(\text{ix} < j \rightarrow \text{old}\)

\(\text{Abs' } \text{t} \text{e} \rightarrow \text{Abs' } \text{t} \text{(go } (\text{SuccIdx' } j) \text{e})\)

\(\text{(shift ZeroIdx' } \text{new})\)

\(\ldots\)

Listing 2. Substitution algorithm implemented against the simplified datatype generated by Ghostbuster

\(\text{upExp} :: (\text{Typeable } \text{env}, \text{Typeable } \text{t}) → \text{Exp } \text{t} → \text{Exp'}\)

\(\text{downExp} :: (\text{Typeable } \text{env}, \text{Typeable } \text{t}) → \text{Exp'} → \text{Maybe } \text{(Exp } \text{t})\)

Referring to the implementation of Listing 2, note that although the \text{Var' } and \text{Abs' } cases constitute environment changing operations, we do not need to manipulate any embedded \text{TypeRep } \text{env } \text{values}; needing to do so would seriously compromise usability, and Ghostbuster is instead able to recover this information automatically (see Sections 2.2 and 2.4).

3.3 Example #2: Template Haskell and Typeclass Deriving

One great feature of Haskell is its ability to automatically derive certain standard typeclass instances such as \text{Show} and \text{Read} for Haskell’98 datatypes. Unfortunately, attempting to do the same for \text{GADTs} results only in disappointment and cryptic error messages from compiler-generated code. However, as we saw in Section 1, we can regain this capability by using Ghostbuster and leveraging derived instances for the simplified datatypes instead.

Similarly, some libraries include Template Haskell [22] routines that can be used to automatically generate instances for the typeclasses of that library. Although these run into problems when applied to \text{GADTs}s, once more we can use Ghostbuster to circumvent this limitation. As an example, we can easily generate \text{JSON} (de)serialization instances for the \text{aeson} package\(^8\) applied to our richly-typed terms:

\(\$(\text{deriveJSON defaultOptions 'Exp'})\)

\(\text{instance } (...) \Rightarrow \text{ToJSON } (\text{Exp } \text{env } \text{t}) \text{ where}\)
\(\text{toJSON } = \text{toJSON } \cdot \text{upExp}\)

\(\text{instance } (...) \Rightarrow \text{FromJSON } (\text{Exp } \text{env } \text{t}) \text{ where}\)
\(\text{parseJSON } \text{v} = \text{do}\)
\(\text{v'} ← \text{parseJSON } \text{v} :: \text{Parser } \text{Exp'}\)
\(\text{return }$ \text{fromMaybe } (\text{error } \text{"\ldots"}) \text{ (downExp } \text{v'})\)

These examples demonstrate that Ghostbuster enables a synergy with existing Haskell libraries and deriving mechanisms, providing a convenient method to lift these operations to \text{GADTs}.

\(^7\)The environment type \text{env} needs to be provided by client (checked mode) because otherwise it is ambiguous. For example, the constant term \text{Con 42} can be typed in any environment.

\(^8\)We simultaneously request erased versions of \text{Idx} and \text{Typ} using the same settings, but elide those for brevity.

\(\text{https://hackage.haskell.org/package/aeson}\)
4. Core Language Definition

Before covering host-language-specific aspects of our Ghostbuster implementation, we first formalize a core language to facilitate the precise description of the transformations performed by the Ghostbuster tool. This core language also serves as the intermediate representation of the Ghostbuster implementation. Although we implement our prototype in Haskell, it is easily extended to generate code for any language that supports GADTs.

The core language definition is given in Figure 3. The input to Ghostbuster is a set of datatype definitions, 

\[ \text{data defs} \]

The term language is used only as an output language for generating up- and down-conversion functions. As such, we are not interested in the problem of type inference for GADTs, rather, we assume type annotations that allow us to use the permissive, natural type system for GADTs [21], which supports decidable checking [9, 24] (but not inference). Our implementation runs a checker for this type system, and, to support checking, case and typecase forms are labelled with their return types as well, though we will elide these in the code through the rest of the paper.

4.1 Syntax

The syntax of terms and types in Figure 3 resembles Haskell syntax with extensions for type representation handling and extra conventions related to type arguments \(\langle K \vec{\tau} S \rangle\) to indicate the erasure level (respectively, type variables which are kept unchanged in the output, and those which are erased in checked and synthesized mode, as discussed in Section 2.2). Without loss of generality, we assume that type constructor arguments are sorted into these kept, checked, and synthesized categories. This simplifies the discussion of which type arguments occur in which contexts, based on position. The implemented Ghostbuster tool does not have this restriction and the status of type arguments are specified in pragmas, as we saw earlier.

A program consists of a number of datatype declarations followed by mutually-recursive value definitions (\(vd\)) and a “main” term \(e\). The generated up- and down-conversions will form a series of \(vd\)s. Terms in our language consist of the lambda calculus, a non-recursive let with explicit type signatures, simple case expressions and ways of creating, casing on, and querying equality of runtime type representations, which we call typerep, typecase, and \(\approx_r\). The \(\approx_r\) operator must work over arbitrary monotype representations, comparing them for equality at runtime. typecase also performs runtime tests on type representations, and enables deconstructing type representations into their component parts—for example, splitting a function type into a input type and output type.

We deviate from the standard presentation of GADTs. Typically, the return type of each constructor is normalized to the form \(T \vec{\tau}\), with any constraints on the output type pushed into a per-data-constructor constraint store \((C)\):

\[ \text{data} \quad \text{constraints} \]

We avoid this normalization. Because we lack type class constraints in the language (and equality constraints over existentially-bound variables can easily be normalized away), we simply omit per-data-constructor constraints. This means that when scrutinizing a GADT with case, we must synthesize constraints equating the scrutinee’s type \(T \vec{\tau}\) with \(T \vec{\tau}_1 \cdots \vec{\tau}_n \) in each \(K_i\) clause and then add this into a constraint store \(C\), which we will use during typechecking (Figure 5). The advantage is that avoiding per-constructor constraints greatly simplifies our definition of the allowable space of input datatypes for Ghostbuster (Section 5). The absence of per-constructor type-class constraints from our core language is also why we require type-indexed typerep values (rather than equivalent Typeable constraints) to observe the type of newly existential type variables (Sections 2.1 and 2.2).

4.2 Type System

The typing rules for our language are syntax-directed and are given in Figures 4 to 7. Many of the typing rules are standard, but a few—in particular Pat, TypeRep, TypeCase, and IfTyEq—are specific to our language and separated into Figure 4. Here the TypeRep and TypeCase rules only cover the type constructor \(T\) cases, the elided rules for the built-in type representations \(T = \text{Existential}\) and \(T = \text{ArrowTy}\) are nearly identical.

We lack a full kind system, but we do track the arity of constructors, with \(T : \vec{\tau} : \Gamma\) as a shorthand for the \(T\) being an arity-\(n\) type constructor. We require that all type constructors be fully applied except when referenced by name through the \(\text{typerep} T\) form.

5. Preconditions and Ambiguity Checking

Before Ghostbuster can generate up- and down-conversion functions, it first performs a sanity check that the datatypes, together with requested parameter erasures, meet all preconditions necessary

\[ \text{precheck} \]

Figure 2. The architecture of the Ghostbuster tool, which processes data definitions in several passes, resulting in pretty-printed Haskell source on disk. Note that only the ingestion and code generation phases are Haskell specific; the ambiguity check through lowering phases are implemented in terms of our core language.

TyRepCon

Figure 6. Equality Theory for the Ghostbuster Type System
We refer to the types whether the erased information can be recovered based on properties which occur in a checked or synthesized context.

The goal of the ambiguity criteria are a concise specification for the tool to generate well-typed conversion functions. Indeed, as we discussed in Section 2 not every erasure setting is valid. We therefore want to create sufficient preconditions such that if these preconditions are met, the Ghostbuster tool is guaranteed to generate a pair of well-typed functions (up, down), such that up-conversion followed by down-conversion is a total identity function. This section details these preconditions and ambiguity criteria.

5.1 Ambiguity Test

The goal of the ambiguity criteria are a concise specification of the class of programs handled by Ghostbuster. These non-ambiguity prerequisites apply per-data constructor, \( K_i \), per-data type that requests a type erasure (nonempty \( \bar{E} \) or \( \bar{S} \) variables). If all constructors of the datatype under erasure individually pass the ambiguity check, then the input program as a whole is valid. For a given data constructor:

\[
K_i :: \forall \bar{E}, \bar{S}, \bar{b}, \bar{r}_1 \rightarrow \cdots \rightarrow \bar{r}_p \rightarrow T \quad (K_i \text{ would refer to all types } \tau \text{ that are not in checked or synthesized context.})
\]

The ambiguity check is concerned with information flow. That is, whether the erased information can be recovered based on properties of the simpler datatype. If not, then these type variables would not be recoverable upon down-conversion and Ghostbuster rejects the program.

5.2 Variables Synthesized on the RHS

For each synthesized type \( \tau' \in \bar{r}_p \) on the RHS, type variables occurring in that type, \( a \in Fv[\tau'] \), must be computable based on:

- occurrences of \( a \) in any of the fields \( \bar{r}_p \). That is, \( 3i \in [1,p] . a \in Fv_{\bar{r}_i} \) from Figure 8; or
- \( a \in Fv[\bar{r}_p] \). That is, kept RHS types; or
- \( a \in Fv[\bar{S}_p] \). That is, \( a \) occurs in the checked (input) type.

Note that the occurrences of \( a \) in fields can be in kept or in synthesized contexts, but not checked. For example, consider our expression \( \text{Exp} \ a \text{ a} \) is determined by the synthesized a component of its sub-expressions, bottoming out at leaf expressions such as constants and variables. In contrast, checked variables in the fields must be created by the down-conversion function as inputs to recursive down-conversion calls on the value’s fields. Thus they cannot be a source of new information to determine synthesized outputs, and we use the \( Fv[\bar{E}] \) rather than the \( Fv[\bar{S}] \) metafunction above. Conversely, notice that we do not worry about applying the above prerequisites to synthesized variables inside fields—these are the outputs of recursive down-conversion calls. Their computability is left to an inductive argument (bottoming out at “leaf” constructors such as \( \text{Exp’s Con} \)).

5.3 Type Variables in Checked Context

All types in checked context in \( \tau_1 \ldots \tau_p \) are implicit arguments to the down-conversion function that will process that field. Thus for all \( \tau_i \) in checked context, all \( a \in Fv[\tau_i] \) must be computable based on information available at that point, which includes:

- kept or checked variables in the \( \text{RHS} \), \( a \in Fv[\tau_i] \cup Fv[\bar{E}] \)
- occurrences of \( a \) in non-erased context within any field
- occurrences of \( a \) in \( Fv[\bar{S}_i] \), for other fields \( \tau_i \) that have already been processed before the field containing \( \tau_i \).

This last case—inter-field dependencies—can be found in the \( \text{Abs} \) case of our expression language (Section 3.1): \( \text{Abs} :: \text{Typ} a \rightarrow \text{Exp} (e, a) b \rightarrow \text{Exp} e (a \rightarrow b) \)

Recall that in our example, given \( \text{Exp} \ a \) \( e \) we erase \( e \) in checked mode and \( a \) in synthesized mode. Thus the type \( (e, a) \) is in checked context, so how is it determined? It cannot be resolved using \((a \rightarrow b)\) on the \( \text{RHS} \), as this is a synthesized type (meaning it is an output of the down-conversion function); it must be determinable from the other fields of the constructor, in this case \( \text{Typ} a \) is.

For a type in checked context, we must be able to determine which fields to examine in order to determine what the checked type should be. This requires that any inter-field dependencies do not form a cycle. As an example, we cannot erase the type \( \tau \) from \( \text{Loop} \), because the types \( a \) and \( b \) in the fields of the constructor are in checked mode but depend on each other:

\( \text{--# Ghostbuster: synthesize t #=} \quad \text{-- invalid!} \)
\( \text{data} \) \( \text{Loop} \ t \) \( \text{where} \)
\( \text{MLoop} :: \text{T a b} \rightarrow \text{T a b} \rightarrow \text{Loop} (a, b) \)

\( \text{--# Ghostbuster: check a, synthesize b #=} \)
\( \text{data} \) \( \text{T a b} \) \( \text{where} \)
\( \text{MxT} :: \text{a} \rightarrow \text{b} \rightarrow \text{T a b} \)

For simplicity our formal language assumes that fields are already topologically sorted so that dependencies are ordered left to right. That is, a field \( \tau_{i+k} \) can depend on field \( \tau_i \). In the case of \( \text{Abs} \), \( a \in Fv[\bar{E}] \) and \( \tau_i = \text{Typ} a \) occurs before \( \tau_2 = \text{Exp} (e, a) b \), therefore Ghostbuster accepts the definition.

5.4 Gradual Erasure Guarantee

One interesting property of the class of valid inputs described by the above ambiguity check is that it is always valid to erase fewer type variables—to change an arbitrary subset of erased variables (either \( \bar{E} \) or \( \bar{S} \)) to kept (\( \bar{E} \)). That is:

**Theorem 1** (Gradual erasure guarantee). For a given datatype with erasure settings \( K, \bar{E} = \bar{E} \bar{S} \bar{T} \) and \( \bar{S} = \bar{S} \bar{T} \bar{S} \), then erasure settings \( K' = (\bar{E} \bar{T} \bar{S}) \), \( \tau' = \bar{T} \bar{S} \bar{T} \bar{S} \) will also be valid.

**Proof.** The requirements above are specified as a conjunction of constraints over each type variable in synthesized or checked position. Removing erased variables removes terms from this conjunction.
We now describe the core translation algorithms used in Ghostbuster.

### 6.2 Up-conversion Generation

In order to generate the up-conversion function for a type \( T \), we instantiate the following template:

\[
\begin{align*}
\text{up}T' & : \text{TypeRep } c \rightarrow \text{TypeRep } s \rightarrow T_i \ T k \ \tau \ \pi \rightarrow T'_i \ \kappa \\
\text{up}T' & \ \ \ \text{cl}\_\text{typerep} \ldots \text{sn}\_\text{typerep} \ \text{orig} = \text{case } \text{orig} \ \text{of} \\
K_j \ \text{let } \phi & \rightarrow \text{unify}(T \ k \ c \ s, \ T k \ \tau \ \pi) \\
K_{\text{tyrerp}} & = \text{map} \ (\lambda \gamma \rightarrow \text{bind}(\phi, \gamma), \ \text{buildTyRep}(r))) \\
\text{getTyReps}(K) & \\
\text{in} \\
K_j' & \text{Ktyrerp} \\
\text{dispatch}_1(\phi, \ x_1, \ \text{phi}(\tau_1)) \ldots \text{dispatch}_1(\phi, \ x_p, \ \text{phi}(\tau_p))
\end{align*}
\]

The Supplemental Material (Section B) includes the full, formal specification of \( \text{up}T' \) generation, but the procedure is straightforward; pattern match on each \( K_j \) and apply the \( K_j' \) constructor. The complexity is in the type representation management of the \( \text{bind} \) and \( \text{dispatch}_1 \) operations. Here we follow a naming convention where a type variable \( k \) is witnessed by a type representation bound to a term variable \( k \_\text{typerep} \). Ghostbuster performs a renaming of type variables in data definitions to ensure there is no collision between the variables used at the declaration head \( T \ T k \ \tau \ \pi \) and those used within each constructor \( K_j \). For example, this already holds in \( \text{Exp} \) where we used env\/ans interchangeably with \( n/a \).

In the let-binding of \( \phi \) above, we unify the type of \( \text{orig} \) with the expected result type of \( K_j \). This uses a unification function that is part of a type checking algorithm based on the type system of Figures 4 to 7. Because we use \( K \in \pi \) variables to refer to the type of the input, \( \text{orig} \), this gives us a substitution binding these type variables. For example, in the \( \text{Abs} \) case of our expression language (Section 3.1):

\[
\begin{align*}
\text{Abs} & :: \text{Typ } r \rightarrow \text{Exp } (e, \ r) \ a \rightarrow \text{Exp } e \ (r \rightarrow a)
\end{align*}
\]

unification yields:

\[
\phi = \{ \text{env} := e, \ \text{ans} := (r \rightarrow s) \}
\]

It is the job of \( \text{bind} \) to navigate this substitution in order to create type representations for type variables mentioned in \( \phi \), such as \( r \). Here, getting to \( r \) requires digging inside the type representation for \( \text{ans} \) using a \( \text{typecase} \) expression. Because the type representation added to \( K_j' \) will always be of the form \( \text{TypeRep} a \) (for type variable \( a \)), this is all the call to \( \text{bind} \) must do to create the type representations that decorate \( K_j' \). Note that there may be multiple occurrences of \( r \in \phi \), and thus multiple paths that bind might navigate; which path it chooses is immaterial.

#### Type representation construction in dispatch

The \( \text{dispatch}_1 \) function is charged with recursively processing each field \( f \) of \( K_j \). Based on the type of \( f \) this will take one of two actions:

- Opaque object: return it unmodified.
- Ghostbusted type \( T \): call \( \text{up}T \).

In the latter case, it is necessary to build type representation arguments for the recursive calls. This requires not just accessing variables found in \( \phi \), but also building compound representations such as for the pair type \( (e, r) \) found in the \( \text{Abs} \) case of \( \text{Exp} \).

Finally, when building type representations inside the \( \text{dispatch}_1 \) routine, there is one more scenario that must be handled: representations for pre-existing existential variables, such as the type variable \( a \) in \( \text{App} \):

\[
\text{App} :: \text{Exp } e \ (a \rightarrow b) \rightarrow \text{Exp } e \ a \rightarrow \text{Exp } e \ b
\]

In recursive calls to \( \text{upExp} \), what representation should be passed in for \( a \)? We introduce an explicit \( \text{ExistentialType} \) in the output language of the generator which appears as an implicitly defined datatype such that \( \text{typerep} \text{Existential} \) is valid and has type \( \forall a. \text{TypeRep} a \).

#### Theorem 2 (Reachability of type representations). All searches by \( \text{bind} \) for a path to \( v \) in \( \phi \) succeed.

**Proof.** By contradiction. Assume that \( v \notin \phi \). But then \( v \) must not be mentioned in the \( T_l \ T k \ \tau_1 \ \pi \) return type of \( K_j \). This would mean that \( v \) is a preexisting existential variable, whereas only newly existential variables are returned by \( \text{getTyReps} \).

### 6.3 Down-conversion Generation

Down-conversion is more challenging. In addition to the type representation binding tasks described above, it must also perform runtime type tests (\( \approx \)) to ensure that constraints hold for formerly...
erased (now restored) type variables. The type signature of a down-converter takes type representation arguments only for checked type variables; synthesized types must be computed:

\[
downT_i : \text{TypeRep} \ c \to T'_i \ K \to \text{Sealed} T'_i \ K \ ?
\]

If the set of synthesized variables is empty, then we can elide the \text{Sealed} return type and return \( T'_i \ K \ c \) directly. This is our strategy in the Ghostbuster implementation, because it reduces clutter that the user must deal with. However, it would also be valid to create sealed types which capture no runtime type representations, and we present that approach here to simplify the presentation.

To invert the \text{up} function, \text{down} has the opposite relationship to the substitution \( \phi \). Rather than being \textit{granted} the constraints \( \phi \) by virtue of a \textit{GADT} pattern match, it must test and witness those same variables; synthesized types must be computed: the user must deal with. However, it would also be valid to create sealed types which capture no runtime type representations, and we present that approach here to simplify the presentation.

\[
downT_i, \ c1_{\text{typerep}} \ldots \ c_n_{\text{typerep}} \ \text{lower} =
\]

\[
\text{case} \ \text{lower} \ of
\]

\[
\begin{align*}
K'_j & \ \text{ex}_\text{typerep} \ldots f_1 \ldots f_p \\
\hspace{1em} \text{let} \ \phi_0 = \ldots \ \text{in}
\end{align*}
\]

\[
\text{openConstraints}(\phi_0, \text{openFields}(f_1 \ldots f_p))
\]

\[
\text{where}
\]

\[
\text{openConstraints}(\phi, \text{body}) = \text{bod}
\]

\[
\text{openConstraints}(a := b : \phi, \text{bod}) =
\]

\[
\begin{cases}
\text{if} \ a_{\text{typerep}} \ \Rightarrow b_{\text{typerep}} \ \text{then} \ \text{openConstraints}(\phi, \text{bod}) \\
\text{else} \ \text{genRuntimeTypeError}
\end{cases}
\]

\[
\text{openConstraints}(a := T \ \tau_1 \ldots \tau_n : \phi, \text{bod}) =
\]

\[
\text{typecase} \ a_{\text{typerep}} \ \text{of}
\]

\[
(T \ \tau) \ a1_{\text{typerep}} \ldots an_{\text{typerep}} \to
\]

\[
\text{openConstraints}(a1 := \tau_1, \ldots an := \tau_n : \phi, \text{bod})
\]

\[
\rightarrow \ \text{genRuntimeTypeError}
\]

Again, a more formal and elaborated treatment can be found in the Supplemental Material (Section B). Above we see that \text{openConstraints} has two distinct behaviors. When equating two type variables, it can directly issue a runtime test. When equating an existing type variable (and corresponding \_typerep term variable) to a compound type \( T \ \tau \), it must break down the compound type with a different kind of runtime test (\textit{tycase}), which in turn brings more \_typerep variables into scope. We elide the \((\rightarrow)\) case, which is isomorphic to the type constructor one. Note that \((\Rightarrow)\) works on any type of representation, but this algorithm follows the convention of only ever introducing variable references (e.g. \( a_{\text{typerep}} \)) to “simple” representations of the form \text{TypeRep} a.

Following \text{openConstraints}, \text{openFields} recursively processes the field arguments \( f_1 \ldots f_p \) from left to right:

\[
\text{openFields}(f_1 : T \ \tau_1 \cdots \tau_n : \text{rst}) =
\]

\[
\text{case} \ \text{openRecursion}(\phi_0, f) \ \text{of}
\]

\[
\begin{cases}
\text{Sealed} f \ \text{e}_\text{typerep} \ f' \to
\end{cases}
\]

\[
\text{openConstraints}(\text{unify}(f'_{\text{typerep}}, \tau_1)
\]

\[
, \text{openFields}(\text{rst})
\]

\[
\text{openFields}(f_1 : T : \text{rst}) =
\]

\[
\text{let} \ f' = f \ \text{in} \ \text{openFields}(\text{rst})
\]

Here we show only the type constructor \((T \ \tau_1 \cdots \tau_n)\) case and the “opaque” case. We again omit the arrow case, which is identical to the type constructor one.

As before with \textit{dispatch}, the \textit{openRecursion} routine must construct type representations to make the recursive calls. Unsealing the result of a recursive call reveals more constraints that must be checked. For example, in the \texttt{add} case of \texttt{Exp}, both recursions must synthesize a return type of \texttt{Int} and thus a type representation inside the \text{Sealed} type of \( (\text{typerep} \ \texttt{Int}) \). Likewise, in the \texttt{App} case the function input and the argument types must match. \text{openConstraints} ensures these synthesized values are as expected before returning control to \text{openFields} to process the rest of the arguments.

Finally, in its terminating case, \text{openFields} now has all the necessary type representations in place that it can build the type representation for \text{Sealed}T. Likewise, all the necessary constraints are present in the typing environment—from previous \textit{typecase} and \((\Rightarrow)\) operations—enabling a direct call to the more strongly typed \( K_j \) constructor.

\[
\text{openFields}(\phi) =
\]

\[
\text{Sealed} T_i, \ \text{buildTyRep}(a_{\text{typerep}}, \text{typerep}) (K_j \ f'_1 \cdots f'_p)
\]

The result of code generation is that Ghostbuster has augmented the \textit{prog} with up- and down-conversion functions in the language of Figure 3, including the \textit{tycase} and \((\Rightarrow)\) constructs. What remains is to eliminate these constructs and emit the resulting program in the target language, which, in our prototype, is Haskell.

### 6.4 Validating Ghostbuster

We are now ready to state the main Ghostbuster theorem: up-conversion followed by down-conversion is the identity after unsealing synthesized type variables.

**Theorem 3. Round-trip** Let \( \text{prog} \) be a program, and let \( T = \{(T_1, K_1, c_1, s_1), \ldots (T_n, K_n, c_n, s_n)\} \) be the set of all datatypes in \( \text{prog} \) that have variable erasures. Let \( D = \{D_1, \ldots , D_n\} \) be a set of dictionaries such that \( D_i = (D_i, s, D_i) \) contains all needed \text{tyReps} for the synthesized and checked types of \( T_i \). We then have that if for each \( (T_i, K_i, c_i, s_i) \) in \( T \) that \( T_i \) passes the ambiguity criteria, then Ghostbuster will generate a new program \( \text{prog}' \) with bused datatypes \( T' = \{(T'_1, k_1), \ldots (T'_n, k_n)\} \), and functions \( \text{up}T_i \) and \( \text{down}T_i \) such that

\[
\forall e \in \text{prog}, \ \text{prog} \vdash e ::= T_i k_i c_i s_i \land (T_i, k_i, c_i, s_i) \in T \implies \text{prog}' \vdash (\upT_i D_i e) ::= T'_i k_i, \text{where} (T'_i, k_i) \in T' \quad (1)
\]

and

\[
\forall e \in \text{prog}, \ \text{prog} \vdash e ::= T_i k_i c_i s_i \land (T_i, k_i, c_i, s_i) \in T \implies \text{prog}' \vdash (\downT_i D_i c \upT_i D_i e) \\
\equiv (\text{Sealed} T_i D_i s, c :: \text{Sealed} T_i K_i c_i) \quad (2)
\]

The full proof including supporting lemmas can be found in the Supplemental Material (Section C). We provide a brief proof-sketch here.

**Proof Sketch.** We first show by the definition of up-conversion that given any data constructor \( K \) of the correct type, that the constructor will be matched. Proceeding by induction on the type of the data constructor and case analysis on \textit{bind} and \textit{dispatch} we then show that the map of \textit{bind} over the types found in the constructor \( K \) succeeds in building the correct \text{tyReps} needed for the checked fields of \( K \). After showing that every individual type-field is up-converted successfully and that this up-conversion preserves values, we are able to conclude that since we have managed to construct the correct type representations needed for the up-converted data constructor \( K' \), and since we can successfully up-convert each field of \( K \) that the application of \( K' \) to the \text{tyReps} for the newly-existent types and the up-converted fields is well-typed and that the values that we wish to have preserved have been kept.

To show that down-conversion succeeds, we first show that given any data constructor \( K' \) of the correct type that the down-conversion function will match it. We then proceed by case analysis on the code-path executed on the right-hand-side of the \texttt{case} clause that matched the data constructor: we show that \textit{openConstraints} succeeds in deriving suitable type representations for the call
to openRecursion to succeed in constructing the correct down-converted datatypes for each of the busted recursive datatypes in the fields of \( R' \). We then use this to show that openFields will succeed in down-converting the busted types that it encounters. We then use the fact that openFields has successfully down-converted the types it has encountered, coupled with the success of constructing suitable type representations to show that we are finally able to successfully construct the down-converted sealed type.

7. Implementing Ghostbuster for Haskell

The Ghostbuster prototype tool is a source-to-source translator, which currently supports Haskell but could be extended to other languages that incorporate GADTs. To build a practical tool implementing Ghostbuster, we need to import data definitions from, and generate code to, a target host language. Because our prototype targets Haskell, we extended our core language slightly to accommodate certain Haskell features of data definitions such as bang patterns. For the most part, code generation is a straightforward translation from our core-language into Haskell using the haskell-src-exts package,\(^{10}\) which we subsequently pretty-print to file. If erasure results in Haskell’98 datatypes, we add deriving clauses to the simplified datatypes for the standard typeclasses such as Show.

7.1 Current Limitations

Our current prototype comes with some limitations. Yet, as we will see in Section 8.2, a great many of the datatypes found in the wild are supported.

Runtime type representation As mentioned in Section 2.1, we require type-indexed TypeRep values, which are scheduled to appear in GHC-8.2. In the meantime, we use our own representation of runtime types synthesized on demand by the Ghostbuster tool and described in the Supplemental Material (Section A.3).

Advanced type system features There are some features we support indirectly by allowing them in the “opaque” regions of the datatype which Ghostbuster-generated code need not traverse, but we do not model explicitly in our core language. This currently includes type families [7, 20] and type classes [11, 19].

Erased datatypes as type parameters As we saw in Section 2.4, Ghostbuster does not allow datatypes undergoing erasure to be used as arguments to other type constructors, for example \( \text{map}\). If available, we could lean on a Functor instance for that type, but in general there is not a single, clearly defined behaviour. Future work may allow a user to specify how Ghostbuster should traverse under type constructors to continue the erasure and conversion processes.

8. Evaluation

8.1 Runtime Performance

This section analyzes the performance of the conversion routines generated by Ghostbuster. Benchmarks were conducted on a machine with two 12-core Xeon E5-2670 CPUs (64-bit, 2.3GHz, 32GB RAM) running GNU/Linux (Ubuntu 14.04 LTS), using GHC version 7.10.1 at -O2 optimization level. Each data point is generated via linear regression using the criterion package.\(^{11}\)

Figure 9 compares the performance of the Ghostbuster generated conversion routines for our simple expression language (Section 3.1). We generated large random programs that included all of the important cases of up- and down- conversion (Abs, kpp, etc.), and report the time to convert programs containing that number of terms.

Ghostbuster achieves comparable performance to a manually written up-conversion routine. The hand-written written down-conversion routine, however, which uses embedded Typeable class constraints is significantly slower than the Ghostbuster generated version with embedded TypeRep values. Profiling reveals that our generated TypeRep encodings were more efficient than dictionary passing with Data.Typeable. However, this may be an artifact of the closed-world simplification we used to generate our TypeRep values, so this performance advantage may disappear once we transition to open-world, type-indexed Typeable arriving in GHC-8.2.

Even so, the size of the Ghostbuster generated up- and down-conversion functions are comparable to the Data.Typeable based implementation:

<table>
<thead>
<tr>
<th>Contender</th>
<th>SLOC</th>
<th>Tokens</th>
<th>Binary size</th>
</tr>
</thead>
<tbody>
<tr>
<td>Ghostbuster</td>
<td>198</td>
<td>1426</td>
<td>1MB</td>
</tr>
<tr>
<td>Data.Typeable</td>
<td>122</td>
<td>1011</td>
<td>1MB</td>
</tr>
<tr>
<td>Hint</td>
<td>78</td>
<td>451</td>
<td>45MB</td>
</tr>
</tbody>
</table>

For the down-conversion process, we also compare against using GHC’s interpreter as a library via the hint package.\(^{12}\) Due to the difficulty of writing the down-conversion process manually, it is appealing to be able to re-use the GHC Haskell type-checker itself in order to generate expressions in the original GADT. In this method, a code generator converts expressions in the simplified type into an equivalent Haskell expression using constructors of the original GADT, which is then passed to \( \text{eval}\) as a string and interpreted, with the value returned to the running program. Unfortunately: (1) as shown in Figure 9, this approach is significantly slower than the alternatives; (2) the conversion must live in the IO monad; (3) generating strings of Haskell code is error-prone; and (4) embedding the entire Haskell compiler and runtime system into the program increases the size of the executable significantly.

Nevertheless, before Ghostbuster, this runtime interpretation approach was the only reasonable way for a language implemented in Haskell with sophisticated AST representations to read programs from disk. One DSL that takes this approach is Hakaru.\(^{13}\)

8.2 Package Survey

We conclude our experimental evaluation by testing our prototype implementation against all 9026 packages currently available on haskell.org, the central open source package archive of the Haskell community. We seek to gather some insight into how many GADTs exist “in the wild” which might benefit from the automated up- and down-conversions explored in this work.

In this survey, we extract all of the ADT and GADT datatype declarations of a package, and group these data declarations into connected components. We elide any connected components where none of the data declarations are parameterised by a type variable, or do not contain at least one GADT. For each connected component, we then vary which type variables are kept, checked, or synthesized, and attempt to run ghostbuster on each configuration. For connected components containing many data types and/or type variables this can yield a huge search space, so we explore at most ten thousand erasure variants for each connected component. A summary of the results are shown in Table 1.

As discussed in Section 5, our current design has some restrictions on what datatypes and erasure settings it will accept. However, out of the variants explored, ghostbuster was successfully able to erase at least one type variable in 2,582,572 cases. Moreover, out

14. Related Work

Ornaments [10, 12, 15], from the world of dependent type theory, provides an interesting theoretical substrate for moving between inductive data structures that share the same recursive structure, where one type is refined, or ornamented, by adding and removing information. Unlike ornaments, we focus on bidirectional conversions from a richer to simpler type. Recent progress has been made in bringing ornaments from a theoretical topic to a practical language [28]. This prototype is semi-automated and leaves holes in the generated code for the user to fill in, rather than being an entirely in language and fully-automatic abstraction like Ghostbuster.

The eqT of Haskell’s Typeable class and the (typecase≡+) and TypeStep of our core language, are both similar to typecase and dynamic from Abadi et al. [1, 2]. However, while typecase (from dynamic) allows querying the type of expressions, it does not inject type-level evidence about the scrutinee into the local constraints the way that GADT pattern matching (and our typecase) do.

Another closely related work is on staged inference [23], which formulates dynamic typing as staged checking of a single unified type system. While the mechanism is different, functions over Ghostbusted types defer type-checking obligations until down-conversion. Likewise, Haskell’s deferred type errors [27] are related, but are a coarse-grained setting at the module level and hence not practical for writing code against GADTs while deferring type-checking obligations.

The Yoneda lemma applied to Haskell provides a method of encoding GADTs as regular ADTs. While this encoding does not offer the benefits of Ghostbuster simplified types because: (1) the encodings include function types, which preclude Show/Read deriving, and (2) the encoding cannot actually enforce its guarantees in Haskell due to laziness (lack of an initial object).

F# type providers [26] are related to Ghostbuster in that both automatically generate datatype definitions against which developers are expected to write code. Type providers do not include GADTs, but deal with type schemas that are too large (e.g. all of Wikipedia) or externally maintained (e.g. in a database) and must be populated dynamically, whereas Ghostbuster deals with maintaining simplified types for existing GADTs.

Checking whether input-output tags are consistent in a logic program is often approximated in practice based on a dependency graph of the variables. For example, the Mercury programming language [25] has tags: input, output, deterministic. Our ambiguity checking process is similar.

Ou et al. [18] define a language that provides interoperability between simply-typed and dependently-typed regions of code. Both regions are encoded in a common internal language (also dependently-typed), with runtime checks when transitioning between regions. Similarly, the Trellys project [6] includes a two-level language design where each definition is labelled logical or programmatic. Because of the shared syntax, one can migrate code from programmatic to logical when ready to prove non-termination.

It is folklore in dependently typed programming communities (Idris, Agda, etc.) that if you need to write a parser for a compiler, you would parse to a raw, untyped term and write a type-checking function (i.e. down-conversion) manually. To our knowledge there are not currently any tools that automate this process. However, most fully dependent languages make these type checkers easier to write than they are in Haskell.

Some types were written in GADT syntax that didn’t need to be.

10. Conclusion

We’ve shown how Ghostbuster enables the automatic maintenance of simplified datatypes that are easier to prototype code against. This resulted in some performance advantages in addition to software engineering benefits. Because of these advantages, we believe that in the coming years gradualization of type checking obligations for advanced type systems will become an active area of work and widely-used language implementations may better support gradualization of type-checking obligations directly.
